ABSTRACT

In recent years, awareness of energy poverty has gained increasing attention in European countries. Comparative country studies can enhance our understanding of the causes and effects of this growing problem. This paper proposes a new model for the analysis of energy poverty. We define a theoretical framework and model to estimate an energy poverty frontier. The estimated frontier indicates the minimum level of energy poverty that a country can achieve given its income level, energy prices, energy intensity, and other country-specific features. We apply the approach to a sample of 30 European countries during the period 2005–2018. This allows us to contrast whether policy measures aimed at reducing the poverty among vulnerable individuals and households have been effective. The results indicate that financial aid aimed at vulnerable groups, reductions in energy prices, and improvements in energy efficiency have been beneficial against energy poverty. These factors may partly explain why, despite the negative income impact of the financial crisis, we found a steady and general energy poverty reduction during the period in almost all the countries analysed.

1. Introduction

Poverty takes many different forms and is a challenge faced by all countries across the world. In general, it is a central social policy issue for most governments. There is a vast literature on the socioeconomic that relates income, natural resources, poverty, and inequality (e.g., Dollar and Kraay, 2002; Zeb et al., 2014; Apergis and Katsaiti, 2018). Better understanding of poverty and its determinants is the basis for the design of effective social policies aimed at alleviating poverty (Collier and Dollar, 2002).

The present study analyses the determinants of energy poverty as a specific form of poverty that is gaining increasing policy attention. Indeed, affordability is one of the main pillars of sustainable energy transition. Energy poverty is often defined as a situation "where individuals are not able to adequately heat their homes or meet other energy service needs at affordable cost" (Pye et al., 2015, p.64).¹

This topic has attracted considerable academic, political, and policy interest in the past decades around all the continents. For instance, in Oceania (Awaworyi Churchill et al., 2020; Awaworyi Churchill and Smyth, 2020), in Asia (Jiang et al., 2020; Khandker et al., 2012), in America (Pablo et al., 2019; Mohr, 2018), or in Africa (Nussbaumer

et al., 2012). Europe, a pioneer in the definition of energy poverty with the studies of Boardman (1991) and Bradshaw and Hutton (1983), has shown an increased interest in this issue, being a much-debated topic at the European Union (EU) level (Bouzarovski and Thomson, 2020).

Energy Economics

In recent years, both the EU and the member states are aiming to address this problem. According to recent reports from the European Commission,² approximately 34 million Europeans were unable to keep their homes adequately warm in 2018. Tackling a problem of this magnitude is a major challenge. Energy poverty has become a political priority since the 2018–19 approval of the Clean Energy for all Europeans Package (CEP) that addresses issues related to energy poverty such as energy efficiency or energy security. Comparative country studies can enhance our understanding of the causes and effects of this problem.

Starting from the premise that the optimum degree of energy poverty for a country is zero, a number of factors challenge this objective. The present study aims to explore the determinants of energy poverty in a sample of European countries, given their income and energy prices, and taking into account their particular characteristics (e.g., income inequalities and energy efficiency, among others). Also, we analyse the tools to reduce energy poverty. It can be reduced indirectly by reducing

¹ In recent years, attention is also being paid to energy services such as to achieve adequate levels of indoor cooling (Thomson et al., 2019).

² https://ec.europa.eu/energy/topics/markets-and-consumers/energy-consumer-rights/energy-poverty_en?redir=1#eu-projects-tackling-energy-poverty.

general poverty or directly by targeting energy poverty as a specific social policy priority. Examples of the latter are the establishment of specific measures to increase energy efficiency or cut energy prices. Also, access to gas network can reduce household energy spending as gas is the main source of space heating for households and inter-fuel competition can also reduce electricity prices (Meier et al., 2013). Understanding the energy poverty phenomenon is crucial in order to introduce efficient policy measures (Primc and Slabe-Erker, 2020). For example, energy poverty experienced by high-income households due to rising energy prices requires different policies than energy poverty from poor housing energy efficiency or poor access to modern energy. They also found that reducing energy poverty is much more complicated for the member states faced with above-average energy poverty (energy-poverty trap).

A number of studies have analysed the determinants of energy poverty in Europe from a microeconomic point of view at the individual or household level (see, e.g., Llorca et al., 2020; or Siksnelyte-Butkiene et al., 2021). However, the literature comparing energy poverty across the European countries is scarce. Thomson and Snell (2013) use crosssectional data from Eurostat EU-SCIL (European Union Statistics on Income and Living Conditions) for 2007 to analyse the explanatory factors for energy poverty at the household level. Their results indicate that energy poverty is more pronounced in southern and eastern European countries and in rural areas. Dubois and Meier (2016) explore an analytical framework of energy poverty using a sample of 28 EU countries for the period 2007-2014, showing that energy poverty varies significantly across countries. While in some cases the main problem is energy services deprivation for a large share of the population, in other countries it is predominantly concentrated in certain groups of househols. Bouzarovski and Tirado Herrero (2017) analyse territorial inequalities through a descriptive analysis. They distinguish between three groups of countries in Europe (north and west, east, and south) and find that energy poverty is more prevalent in the periphery than in the centre.

Using also macro-level data, Cadoret and Thelen (2020) contrast the existence of the Kuznets curve between energy poverty and GDP per capita in Europe taking advantage of a panel of data from 28 European countries for the period 2004-2017 collected from Eurostat's EU-SILC survey. They find that an improvement in the standards of living of the population has made it possible to reduce energy poverty, particularly in southern and eastern Europe. However, they also find that more economic growth will not systematically induce less precariousness, so measures in favour of energy efficiency and/or measures aimed at increasing the purchasing power of households must be put in place at the national level. Filippidis et al. (2021) use a panel dataset from over 200 countries for the period 2000-2019 to contrast the Energy-Environmental Kuznets Curve hypothesis. They find that stronger economic growth positively affects electricity production from renewable sources and reduces electricity production from coal. Moreover, an increase in renewable energy consumption reduces income inequality.

In this study, we propose the use of a frontier methodology, which is standard for the analysis of the technological efficiency of companies or countries, but its application to the study of poverty or inequality is uncommon.³ The main novelty of our study is to present a new theoretical framework and methodological approach to analyse the socioeconomic determinants of energy poverty. The study contributes to the literature by identifying the determinants of energy poverty using a stochastic frontier analysis approach. This methodology will allow us to quantify and better understand the level the energy poverty of European countries and their potential for improvement.

To our knowledge no previous studies have estimated an energy poverty frontier function. This frontier function envelopes the data,

(2019) or Valls Fonayet et al. (2020).

while not allowing the observations to be below the estimated frontier. The most efficient countries are those that achieve, ceteris paribus, the lowest energy poverty levels given their per capita income and the country's own idiosyncrasy. Once the energy poverty frontier is estimated, it is possible to analyse the observations that are above the estimated frontier and obtain an efficiency ranking of the countries, ordering them by their distance from the energy poverty frontier, given its income level and other country-specific characteristics. In this sense, the concept of frontier is relative and not absolute.

The analysis of the determinants that prevent a country from reaching its minimum level of energy poverty is important from a policy point of view. For instance, policy makers might be interested in evaluating whether specific aids could alleviate energy poverty inefficiency. In this regard, we analyse, among other determinants, whether social protection policies aimed at vulnerable groups affected by a specific set of social risks and needs have reduced energy poverty.

The remainder of the paper is as follows. Section 2 presents the theoretical model on which the study is based. Section 3 presents the proposed empirical model to estimate the energy poverty stochastic frontier. Section 4 describes the data. Section 5 presents the results and discusses policy issues emerging from the estimation of the model. Section 6 concludes.

2. The theoretical model

We define \overline{V}^z as the utility level that allows individuals in a country to live above the energy poverty line (z). We then define the following ratio:

$$EP = \frac{\overline{V}^2}{\overline{V}^0} \tag{1}$$

where $\overline{V}^{\mathbb{Z}}$ represents the utility level obtained from a bundle of goods that would permit people to be above the energy poverty line (energy poverty threshold), and V^0 is the observed utility obtained by the bundle of goods that the consumer actually has. Under these definitions, when $V^0 < \overline{V}^{\mathbb{Z}}$ the consumer will be in an energy poverty situation. Thus, when *EP* takes values greater than one, this index represents energy poverty. In this case, the higher the value of the *EP* index in Eq. (1), the higher the degree of energy poverty.

In logarithmic terms, Eq. (1) is expressed as:

$$lnEP = ln\overline{V}^{z} - lnV^{0} \tag{2}$$

We also assume that, among other objectives, the state seeks to reduce the energy poverty level as much as possible. Given this assumption, the state seeks:

$$\min lnEP = \min \left(ln\overline{V}^{z} - lnV^{0} \right)$$
(3)

such as :
$$V \equiv V(GDP, P)$$
 (4)

where V is the indirect utility function that represents the consumer's maximal attainable utility or well-being with a bundle of goods when faced with a vector of prices (P) and an amount of income. In this study, we are interested in estimating the extent to which a country can potentially reduce its level of energy poverty with a given level of income and prices. Therefore, we consider income as GDP per capita at the aggregate level. V fulfils the following properties:

$$\frac{\partial V(GDP, P)}{\partial GDP} > 0; \frac{\partial V(GDP, P)}{\partial P} < 0$$
(5)

From Eqs. (3) an (4), we obtain:

$$\min lnEP = \min\left(ln\overline{V}^{c} - lnV^{0}(GDP, P)\right)$$
(6)

We can define:

$$lnf(GDP, P) = ln\overline{V}^{z} - lnV^{0}(GDP, P)$$
(7)

where f is the function to minimise. Under these assumptions, f will have a positive relationship with P, and a negative relationship with GDP:

$$\frac{\partial f(GDP, P)}{\partial GDP} < 0; \frac{\partial f(GDP, P)}{\partial P} > 0$$
(8)

The difference between the current energy poverty level (Eq. (2)) and function f that indicates the minimum energy poverty level for a country given its income and prices, is considered as a measure of the efficiency which each country is able to tackle energy poverty.

If we call this difference *u*, we obtain:

$$lnEP = lnf(GDP, P) + u \tag{9}$$

This implies that we can obtain an energy poverty efficiency index of the countries, if we take the ratio of the minimum to the current energy poverty level, which is the same as:

$$exp(-u) = f(GDPP)/EP$$
⁽¹⁰⁾

By definition, the ratio in Eq. (10) is bounded between 0 and 1, and could be considered as a measure of efficiency in relation to what minimum level of energy poverty would be attainable for each country. Moreover, we are interested in identifying the factors that can explain the reasons why a country has an energy poverty index higher than its minimum potential. For instance, policy makers might be interested in knowing whether social protection that encompasses interventions from public or private bodies intended to relieve households and individuals of the burden of a defined set of risks or needs, have been effective. As explained in next section, we tackle this issue allowing the variance of the *u* term to be a function of covariates (i.e., inefficiency determinants) in which we include, among other factors, social protection expenditure.

3. The empirical model

We propose the application of a stochastic frontier analysis approach to estimate an energy poverty frontier function. This allows us to calculate the difference between the minimum energy poverty level feasible for a country (given its income, energy prices, energy intensity, and other factors), and its current level of energy poverty. In other words, we can obtain the potential maximum reduction of energy poverty for the analysed countries. We take advantage of a panel data framework and the application of a True Fixed Effects (TFE) model (Greene, 2005a, 2005b) to control for unobserved country-specific heterogeneity, while we propose a heteroscedastic specification of the inefficiency term to understand the differences in the occurrence of energy poverty among countries.

Considering the previous comments and including a random term to capture noise (ν), Eq. (9) becomes:

$$Ln EP_{it} = \alpha_i + lnf(GDP_{it}, P_{it}) + u_{it} + v_{it}$$
(11)

where *i* indicates country, *t* time, α_i are country dummies that capture time-invariant country characteristics. We assume v_{it} is i.i.d. $N(0,\sigma_v^2)$. Moreover, we follow Wang and Schmidt (2002) who propose a modelling strategy in which the random variable *u* (representing inefficiency), has the following form:

$$u_{it} \sim h_{it}(\mathbf{z}_{it}, \delta) \mathbf{u}^* \tag{12}$$

where $h(.) \ge 0$ is a non-stochastic function (scaling function) of at set of exogenous explanatory variables, z, δ is a vector of parameters to be estimated, and $u^* \ge 0$ is a random variable that follows a half-normal distribution, common to all observations, and does not depend on z-variables.

The model specified in Eq. (12) implies that the inefficiency term, u_{ib} follows a common distribution given by u^* , but each observation is weighted by a different, observation-specific scale of $h_{ii}(z_{ib}, \delta)$. In sum,

the model is specified as:

$$Ln EP_{it} = \alpha_{it} + lnf(GDP_{it}, P_{it}) + u_{it} + v_{it}$$
(13)

$$u_{it} \sim h(z_{it}\delta) \cdot u^* = h(z_{it}\delta) \cdot N^+(\tau, \sigma_u^2) \equiv exp(z_{it}\delta) N^+(\tau, exp(c_u))$$
(14)

$$v_{it} \sim \mathbf{N}^+ \left(\mathbf{0}, \, \boldsymbol{\sigma}_{v}^2 \right) \tag{15}$$

where τ and c_u are constant parameters. As Kumbhakar et al. (2015) point out, an attractive feature of this specification of the model is that it satisfies the scaling property, which captures the idea that the shape of the distribution of u_{it} is the same for all countries. The scaling function h(·) essentially stretches or shrinks the horizontal axis, so that the scale of the distribution of u_{it} changes but its underlying shape does not change. Moreover, modelling heteroscedasticity is justified from an empirical perspective, as the parameters in both the model and the inefficiency estimates can be biased when heteroscedasticity is neglected (Caudill and Ford, 1993).

4. Data

The data used in this study has been collected from Eurostat, the statistical office of the European Union, using the EU-SILC survey, based on data reported by the countries. The period analysed covers 2005–2018. In order to estimate the model (Eqs. (13)–(15)), we first need to proxy our dependent variable, i.e., an energy poverty index. The following sub-section reviews the main measures proposed in the literature to identify energy poverty.

4.1. Measuring energy poverty

Energy poverty is inherently difficult to measure. In the literature different models can be found to approximate it. Following Healy and Clinch (2002) or Thomson et al. (2017), we can distinguish different types of measures of energy poverty. First, a direct and objective measurement (temperature approach), where the level of energy services achieved in the home is compared to a set standard (e.g., Oreszczyn et al., 2006). Second, an also objective expenditure approach, by means of indicators such as income, housing costs or energy costs (e.g., Legendre and Ricci, 2015; or Burlinson et al., 2018). Examples in this category include the 10% rule, which considers that a household in energy poverty uses more than 10% of their income on fuel costs to maintain an adequate temperature at home (Boardman, 1991); the Low Income High Costs (LIHC) approach (Hills, 2012), which considers that a household is in energy poverty on the basis of two criteria: 1) has energy needs higher than the median for the household type, and 2) has an income lower than 60% of the median for the household type; the After Fuel Cost Poverty (AFCP) approach (Hills, 2011), which considers that a household is in energy poverty if its income is 60% less than the median income for its household type (after housing and fuel costs); or the Minimum Income Standard (MIS) approach defined as "having what you need in order to have the opportunities and choices necessary to participate in society" (Bradshaw and Hutton, 1983, p.1). Third, a subjective measure (consensual approach) based on self-reported assessments of indoor housing conditions, for example, whether individuals are able to keep their houses at an adequate temperature (e.g., Bouzarovski and Tirado Herrero, 2017).

Due to their greater availability, the last two types of measurements are the most used. Although objective measures may appear to be more reliable than subjective measures, some studies argue that subjective measures have several advantages, for example, capturing the 'feeling' of material deprivation perceived by individuals (Fahmy et al., 2011). As Garcia Alvarez and Tol (2020) point out, subjective measures allow the

⁴ For a review of energy poverty measures see, for instance, <u>Siksnelyte-Butkiene et al.</u> (2021).

researcher to identify not only the incidence but also the intensity of energy poverty. In sum, although the objective expenditure approach seems to be the more suitable than the subjective one, it is not free from problems. The main drawbacks are associated with the use of thresholds, and the use of actual rather than *required* energy expenditures (Best et al., 2021). For this reason, several studies have combined both measures, that is to say, consensual approach which is subjective, and expenditure approach which is objective (see, e.g., Waddams Price et al., 2012; Kahouli, 2020, Llorca et al., 2020; or Munyanyi et al., 2021).

Also, as Koomson and Danquah (2021) point out, the above measures are mainly employed in studies of developed countries due to the availability of comprehensive data on household energy or fuel expenditures. In developing countries, it is common to find other measures such as the Multidimensional Energy Poverty Index (MEPI), which combines both objective and subjective measures of energy poverty (Feeny et al., 2021; Zhang et al., 2021; or Nussbaumer et al., 2012).⁵ Other indices used in developing countries are for example the composite Household Development Index (HHDI) (Mamidi et al., 2021). Recently, Acheampong et al. (2021), Bajo-Buenestado (2021), Nawaz (2021), Pachauri and Rao (2020) or Falchetta and Mistry (2021) have analysed energy poverty by focusing on the energy supply conditions and the status of household.

In order to achieve the objectives of this work, we need comparable data for different European countries. However, as Thomson et al. (2017) highlight, there is no standardised household micro-data on energy expenditure, energy consumption, or energy efficiency across EU countries. As a result, researchers mainly rely on consensual data concerning the consequences of energy poverty, such as the ability to keep the house adequately warm in winter, arrears on utility bills, and the presence of damp in the home. In this study we use these three indices. Thomson et al. (2017) also point out that as energy poverty is multidimensional, the most desirable approach would be the widest possible combination of indicators to build a detailed picture of energy poverty. We therefore propose the use of a composite index. Different composite indices have been proposed in the literature (see Healy and Clinch, 2002; or Thomson and Snell, 2013). In order to avoid arbitrary weights, we follow Thomson and Snell (2013) weighting, which is the most used in the energy poverty literature (see Bouzarovski and Tirado Herrero, 2017; Cadoret and Thelen, 2020; Primc and Slabe-Erker, 2020). As Bouzarovski and Tirado Herrero (2017) point out, the proposed index is based upon the premise that consensual measures (such as the selfreported inability to keep warm) could be insufficient to capture the complex nature of energy poverty and should be combined with indicators describing the housing and financial conditions of the population in order to obtain a fuller picture (Bouzarovski, 2014; Dubois and Meier, 2016). All in all, following Thomson and Snell (2013), we define the following composite index:

Energy poverty = $0.5 \cdot \text{Inhability} + 0.25 \cdot \text{Arrears} + 0.25 \cdot \text{Housing Faults}$ (16)

where

Inability indicates the percentage of people from the total population who are in a state of enforced inability to keep their home adequately warm.

Arrears is the percentage of people from the total population who are in a state of arrears on utility bills (heating, electricity, gas, water) on time, due to financial difficulties.

Housing Faults captures the percentage of population living in a dwelling with a leaking roof, damp walls, floors or foundation, or rot in window frames or floor.

As far as the weights used are concerned, Thomson and Snell (2013),

analyse four scenarios, in which each of the three energy poverty indicators is assigned a weight. They found similar levels of energy poverty among the four scenarios, and the levels of the energy poverty composites are relatively stable across most European countries for all four scenarios.⁶ Maxim et al. (2016) extend the index defined in Eq. (16) defining the Compound Energy Poverty Indicator (CEPI), which includes two more variables (share of population living in a dwelling not comfortably cool during summertime, and share of population considering their dwelling as too dark). However, they found that CEPI results do not differ significantly from the approach utilised here to construct the energy poverty index.

All in all, *Energy poverty* defined in (16) can be considered a proxy of the energy poverty defined in Eq. (1). A value of *Energy poverty* greater than zero indicates the percentage of the population of a country that has an observed utility V^0 lower than the corresponding to the poverty threshold $V^{\mathbb{Z}}$. For this percentage of the population, *EP* measure in Eq. (1) is greater than 1. The higher the *Energy poverty* index, the higher the rate of energy poverty in a country.

4.2. Explanatory variables

Following the theoretical model in Eq. (9), we include income and prices as explanatory variables:

GDP per capita (in Euro), which is widely used for comparison of living standards within the European Union. This variable has been deflated using the Harmonised Index of Consumer Prices (HICP) (2015 = 100).

Energy prices, which is a weighted average of electricity and gas prices. On the one hand, electricity prices for households are defined as the average national price (in Euro per kWh) including taxes and levies for medium size household consumers (annual consumption until 3500 kWh). On the other hand, gas prices for household consumers are defined as the average national price (in Euro per kWh) including taxes and levies for medium size household consumers (small and medium consumption). We utilise the share of electricity and gas in final energy consumption in household as weights of this average energy price.⁷

Moreover, following Boardman (2010), energy poverty is frequently associated with low income, high fuel costs, and poor energy efficiency. According to this, we model energy poverty based on these factors. In addition to income (per capita GDP) and fuel costs (energy prices), we also include energy intensity, which is often used as a proxy for energy efficiency at country level (IEA, 2014). *Energy intensity* is one of the indicators to measure the energy needs and the structure of the economy. Following Eurostat, this variable reflects the structure of economy and its cycle, general standards of living, and weather conditions in the reference area. Energy intensity is calculated as units of energy consumed per unit of GDP (the indicator is expressed in chain linked volumes).

⁵ This measure has also been applied to developed countries (for example, Awaworyi Churchill and Smyth, 2021; in Australia).

 $^{^{6}}$ In each of the four scenarios, the weights for Inability/Arrears/ Housing Faults are: (0.5/0.25/0.25), (0.25/0.5), (0.25/0.25/0.5), and (0.33/0.33/0.33). We have tried to compare the approach followed in Eq. (16) with another that equally weights the three energy poverty factors. However, in the latter case, when trying to estimate the proposed model, this did not converge.

⁷ The energy price index that we use is similar to the HICP for energy products. Both are Paasche/Laspeyres-type price indices (Eurostat, 2018). In our case, the main advantage is that we have manually created the index in order to be able to adjust it to our specific objectives. Thus, in our index the energy prices are those corresponding to small and medium size household consumers (avoiding consumers from large or very large consumption bands). By doing so, the prices that we have used in the analysis are more in line with the reference prices for the type of consumers that are the object of our analysis (i.e., those more prone to suffer energy poverty).

In addition, in order to capture specific characteristics of the different countries that can affect the energy poverty indices, we include country-specific dummy variables.⁸ These dummies capture time-invariant factors, for example its geographical situation, weather, or geographic conditions. However, the energy poverty frontier can also be affected by time-variant country-specific factors, such as income inequality, energy efficiency or urbanisation degree. With the aim of considering these specific factors, we have also included the following variables in the energy poverty frontier:

Population density. Roberts et al. (2015) and Bouzarovski and Thomson (2020) have found that there is a relationship between population density and energy poverty. We therefore take into account this variable in the analysis by including the variable *Population density,* which indicates the total population (on 1 January each year) per square kilometre. This variable shows how the degree of urbanisation of the different countries has evolved during the period considered.

Elderly. It is the ratio between population over 65 and the total population. This ratio provides information regarding demographics and vulnerable consumers. According to the result obtained by González-Eguino (2015) and Okushima (2019), we expect a positive relationship between energy poverty and the amount of elderly in a country.

Gini index. Several studies have analysed the relationship between energy poverty and inequality (see Bardazzi et al., 2021; or Galvin, 2019). We proxy inequality including the *Gini* index that measures the distribution of income across a population. It is used as a gauge of economic inequality, measuring income distribution. According to Eurostat this index is defined as the relationship of cumulative shares of the population arranged according to the level of equivalised disposable income, to the cumulative share of the equivalised total disposable income received by them. The coefficient ranges from 0 to 100%, with 0 representing perfect equality and 100% representing perfect inequality.

Regarding the *z*-variables that are introduced as inefficiency determinants, we include: *Population Density, Time* (trend variable), *Crisis* (dummy variable that takes value 1 for the period between 2008 and 2013), and *Social protection*.⁹ This variable indicates social protection benefits (as % of GDP) provided to household and individuals affected by a specific set of social and economic risks and needs. The eight main risks and needs that are recognised are: disability, sickness/health care, old age, survivors, family/children, unemployment, housing, and social exclusion.¹⁰ Table 1 shows the descriptive statistics of the data used in this study.

Fig. 1 shows the evolution of the average of the *Energy poverty* index for the whole sample. In general terms, the index increases as of 2008, decreasing as of 2013 with a worsening at the end of the period. The effect of the economic cycle marked by the financial crisis seems clear in this evolution. This phenomenon is also reflected in Fig. 2, where the evolution of Social Protection in Europe is presented. In order to face the adverse effects of the crisis on the most vulnerable groups, social aids soared from 2008 on, with a steady decrease from 2013. However, Figs. 1 and 2 suggest that *Energy Poverty* and *Social Protection* increased in parallel, something that could be interpreted as that social protection aids have been ineffective in alleviating energy poverty.

However, if we analyse the evolution of these variables by country,

 Table 1

 Descriptive statistics.

Variables	Mean	Std. dev.	Minimum	Maximum
Energy poverty	12.88	8.83	2.53	49.10
Inability	11.75	12.01	0.30	67.40
Arrears	11.31	9.30	1.10	44.00
Housing	16.73	7.83	4.20	42.20
GDP per capita	0.03	0.02	0.01	0.10
Energy Prices	0.11	0.04	0.04	0.29

Fig. 1. Evolution of energy poverty index.

Fig. 2. Evolution of social protection benefits.

we observe a positive relationship between *Social Protection* investment and *Energy Poverty* reduction. Thus, in general terms, Figs. 3 and Fig. 4 suggest that countries that invest a high percentage of their GDP in social protection (i.e., Austria, Belgium, Denmark, Finland, France, or the Netherlands) have lower energy poverty rates. However, countries such as Slovakia or Estonia jointly present low energy poverty and social protection levels.

On the other hand, Fig. 5 shows the relationship between *Energy poverty* and *GDP* per capita, with an expected negative relationship. The energy poverty frontier would be defined by the observations that have a lower level of energy poverty by income per capita, but taking into

⁸ This can be seen as a "a brute force maximum likelihood" approach (Filippini et al., 2008) for estimating the TFE model originally proposed by (Greene, 2005a, 2005b).

⁹ Note that *Social Protection* does not 'shift' the frontier for efficient observations, but it is a determinant of inefficiency. Therefore, it should not be included in the energy poverty frontier.

¹⁰ Social benefits (gross) are recorded without deduction of taxes or other compulsory levies payable by recipients. 'Tax benefits' (tax reductions granted to households as part of social protection) are generally excluded.

Fig. 3. Energy poverty index by country.

account other variables that also affect the Energy poverty variable such as energy prices, the degree of urbanisation of the country, the degree of equality in the distribution of wealth, the energy efficiency and other factors that are part of the idiosyncrasy of each country and can affect the prevalence of energy poverty.

In sum, it is necessary to conduct a more exhaustive analysis of the relationship between energy poverty and socioeconomic factors and policies, which motivates the objective of the present paper.

5. Empirical results and discussion

The results obtained from the estimation of the model (Eqs. (13)–(15))¹¹ are shown in Table 2. As expected, and similarly to Cadoret and Thelen (2020), energy poverty has a negative relationship with income and positive with energy prices. Concretely, results indicate that, at the mean, an increase of 1% in *GDP* per capita reduces, on the average of the sample mean, the energy poverty index in 1.45%, and we cannot rule out that this relationship is linear. Also, *Energy Prices* increase energy poverty. An increase of 1% in *Energy Prices* increases, on the average of the sample mean, the potential level of energy poverty by 0.27%. Energy intensity has a significant and positive coefficient indicating, as expected, that countries with higher energy efficiency have more facility to alleviate energy poverty. Concretely, the *Energy Poverty* index will increase, on average, with 0.001% with a one-unit increase in the *Energy*

Intensity index.

An increment in the degree of urbanisation of the country, measured in terms of the density of the population, implies a higher rate of energy poverty. Concretely, a one-unit increase in the density of the population increases the *Energy Poverty* index by 0.007%. As expected, the degree of inequality in the countries, measured by the *Gini* index, implies higher levels of energy poverty in less egalitarian countries. The *Energy Poverty* index will increase 0.025% for an increase of 1% in the *Gini* index.

Once the model is estimated, it is also possible to calculate the marginal effects for the inefficiency determinants that prevent European countries from reaching their minimum level of energy poverty. These marginal effects represent changes in the expected value of the inefficiency term (*u*) when there is a change in the inefficiency determinants, i.e., $\frac{\partial E(u_k)}{\partial z_k}$ (see Appendix A for details). The average marginal effect of *Social Protection* is -0.0143. This means that the *Energy Poverty* index is reduced by 1.43% for 1% increase in the social protection benefits. In other words, this result confirms a positive relationship between *Social Protection* and energy poverty reduction. Efficiency increases as more is spent on social protection aids.

The marginal effects for other determinants also report interesting results. Specifically, an increase in one-unit in *Population Density* means that the country is moving away from its maximum energy poverty reduction by 0.032%. This result implies that the most densely populated (more urbanised) countries are farthest from their energy poverty minimum level. This result is in line with the study by Roberts et al. (2015), which compares the level energy poverty in rural and urban areas of the UK. They find that, on average, the experience of energy poverty in urban areas is longer with a higher probability of energy

¹¹ In the estimation, all variables have been lagged one period (predetermined variables) in order to address the potential endogeneity in the model.

Fig. 4. Social protection by country.

Fig. 5. Energy poverty index and per capita GDP relationship.

poverty persistence. Also, this result can complement those found in Bouzarovski and Thomson (2020), where no differences are found between densely and thinly populated areas when two self-reported indicators of energy poverty (arrears on utility bills and inability to keep warm) are considered. On the other hand, we found a significant effect of the variable *Elderly*. The positive sign of the estimated coefficient indicates that the greater the aging population, the greater the energy poverty index, which evidences the situation of vulnerability of the elderly people in Europe. Concretely, *Energy Poverty* index is increased by 0.52% for 1% increase in the *Elderly* variable. If we take into account

A. Rodriguez-Alvarez et al.

that, with the data from our sample, the ratio between population over 65 and the total population increased by 23.4% between 2005 and 2018, this result may be relevant from a social policy point of view in order to face the needs of the aging population in the European Union.

The financial crisis has had a negative and significant impact on energy poverty. During the financial crisis period, the distance to the energy poverty frontier increased by 9.7% with respect to the non-crisis period. In the past, changes in the price of energy have been viewed as a major cause of energy poverty. However, the financial crisis of 2008 and COVID-19 pandemic in 2020 have shown that sudden negative incomes shocks can quickly become a source of energy poverty. The effect of energy prices on energy poverty is direct and can, for instance, be addressed through price subsidies. However, the effect of economic crisis on income and energy poverty is less direct. The income support mechanisms have the advantage that they enable the recipients to allocate the extra funds among competing needs than allocating them only to energy needs. In the UK, research has shown that Winter Fuel Allowance paid to the elderly was primarily used towards energy bills although this was not a condition for receiving the support (Beatty et al., 2014). Some of this effect has been attributed to the importance of labelling of policy instruments to nudge the recipients in a certain consumption path. Moreover, we have found that time has a positive effect on reducing energy poverty (with a mean energy poverty reduction by 4.1%). This trend is also clearly observed in Fig. 6.

Figs. 7 and 8 report the Energy Poverty Efficiency by country. Fig. 7 shows the means of the indices of energy poverty efficiency according to Eq. (10). Malta, Turkey, and Estonia have the lowest efficiency rates, while France, Sweden, Denmark have the highest. The evolution of the efficiency shown in Fig. 8 seems to corroborate what has already been indicated in Table 2 of results. In general terms, all countries show improvements in the evolution of energy poverty efficiency, with the possible exception of Ireland. Interestingly, it is this country that seems to have a decrease in investment in social protection benefits during the period. Finally, the main descriptive statistics by country are reported in Appendix B.

We can conclude that, for the sample of European countries and the period studied here, which includes the 2008 financial crisis, income support measures for vulnerable groups have been effective in fighting against energy poverty. It is therefore to be expected that measures expressly aimed at alleviating energy poverty will also be (and perhaps even more) effective. Along these lines are the recommendations of the European Union. As Bouzarovski and Thomson (2020) point out, alleviating energy poverty is a key precondition for achieving just transitions towards sustainability. They also point out that at the end of 2016, there were a relatively limited number of policies and actions at the level of the EU and member states related to energy poverty. However, in

recent years, energy poverty has been mainstreamed into various EU directives and member state policies. Thus, several projects have been developed throughout Europe to alleviate energy poverty. For example, as part of the 2018 call of Horizon 2020 Energy Efficiency, three projects have been addressed with this aim (STEP –Solutions to Tackle Energy Poverty–, EmpowerMed and SocialWatt). Other examples are the Clean Energy for all Europeans Package (CEP) and the Green Deal strategy, presented at the end of 2019, that continues and extends the CEP's objectives with the aim of making the EU economy sustainable, and "this transition must be just and inclusive" (p. 2).¹²

Moreover, the recent health crisis has also brought an unprecedented economic crisis that is affecting the entire population, with special incidence on the most vulnerable groups (Bouzarovski and Thomson, 2020). Therefore, due to the consequences of the COVID-19 pandemic, both energy and income poverty are expected to become more acute in the near future (Nagaj and Korpysa, 2020). Against this background, repairing the short-term damage of the crisis, in a way that also involves investing in the long-term future, has become a priority for the EU. This is the centrepiece of the NextGenerationEU and the Recovery and Resilience Facility European programmes.¹³ Member states will be able to use this instrument to carry out sustainable infrastructures and the renovation of the existing housing stock. All of this "will help save money on energy bills, provide healthier living conditions and reduce energy poverty" (p.7).¹⁴

In summary, it is possible to apply different types of measures in European countries to fight against energy poverty. First, financial assistance to vulnerable and marginalised social groups, that this study has found effective. Second, act on energy prices, that we have also found to be positively and significantly related to energy poverty. Third, more specific measures aimed at reducing energy poverty via increases in energy efficiency in line with those proposed by the EU. Our results also support these last measures, finding that increasing energy efficiency has a significant and positive impact on the fight against energy poverty. However, the design and implementation of these specific measures has proven in some cases difficult, as well as their evaluation (Garcia Alvarez and Tol, 2020).

Therefore, these specific measures addressed to improve energy efficiency (e.g., energy retrofits or energy-saving appliances) can be complemented with short-term solutions aimed at improving the financial situation of especially vulnerable groups (see, e.g., Castaño-Rosa et al., 2020; for the case of Spain).

6. Conclusions

New tools that not only explain the incidence of energy poverty but also explain and quantify the effect of the determinants that influence this type of poverty, could be useful for evaluating the different measures and instruments that are used to mitigate this problem. This paper addresses, within an appropriate theoretical framework, the analysis of the determinants that influence energy poverty. The methodology used, based on the estimation of relative frontiers, is used to estimate and explain the maximum potential reduction in energy poverty in a country given its characteristics. It also allows better understanding and quantifying the determinants that facilitate or hinder achieving this potential, for example, to evaluate the effect on energy poverty of policies aimed at protecting vulnerable groups.

Fig. 7. Energy poverty efficiency by country (mean values).

Fig. 8. Evolution of energy poverty efficiency by country.

We applied this methodology to a sample of 30 European countries in the period 2005–2018. As expected, countries with higher economic development (measured by per capita income) and more egalitarian countries have a lower incidence of energy poverty, while higher rates in energy prices exacerbate the problem. Moreover, social protection has been a significant factor in reducing energy poverty. We show that this reduction has been a steady and general trend in almost all the countries analysed. This means that despite the negative and significant effect of the economic cycle (which includes the financial crisis of 2008), it has been possible to contrast the countercyclical effect of these aids, and its contribution to the general improvement in reducing energy poverty.

Energy efficiency measured by the energy intensity is also significant

A. Rodriguez-Alvarez et al.

to reduce energy poverty. Therefore, the results conclude that policies aimed at improving the financial situation of vulnerable groups, reducing energy prices and/or energy efficiency measures can significantly help against energy poverty. On the other hand, the results indicate that energy poverty worsens in urban areas, which may be indicating the presence of energy poverty that hides in large cities.

Finally, note that this study has been carried out at aggregate level, which offers the advantage of being able to make a comparison of the different European countries. However, at this level, the exact causes of energy services deprivation of vulnerable groups cannot be identified. Nevertheless, it is also noteworthy that, although the study is carried out at macro-scale, the model is also applicable at microeconomic level to evaluate factors and policies carried out at the state, provincial or even local level. In this sense, it is possible to compare a region or locality with others within a country. The availability of more detailed data on the individual and household characteristics in terms of income, degree of urbanisation, quality, and type of dwelling among others, will make it possible to obtain more targeted conclusions.

From the model presented in Eqs. (13)–(15), we can obtain the marginal effects (see Kumbhakar et al., 2015). From Eq. (14), we have:

$$E(u_{it}) = exp(z_{it},\delta) E(u^*)$$
 where $u^* \sim N^+(\tau, \sigma_u^2)$

Then,

$$\frac{\partial E(u_{it})}{\partial z_{it}} = \delta exp(z_{it}^{'}\delta)E(u^{*})$$

Being $E(u^*)$ a scalar, which can be calculated from:

$$E(u^*) = \sigma_u \left[\frac{\tau}{\sigma_u} + \frac{\phi\left(\frac{\tau}{\sigma_u}\right)}{\phi\left(\frac{\tau}{\sigma_u}\right)} \right]$$

where ϕ (.)*and* Φ (.) represent the probability density and probability distribution functions, respectively. To get the estimated value, it is possible to replace τ and σ_u by $\hat{\tau}$ and $(1/2\hat{c}_u)$.
